***Abstract*—How can one perform code transformations such as obfuscating transformations or optimizing transformations on code that is assumed to be correct with respect to certain specified behaviour? Will the transformed code preserve the specified behaviour as one expects?**

To achieve the highest levels of assurance that the transformations have maintained correctness of the code, is to prove the two versions of the program (before and after the transformation) is equivalent. Total equivalency between the two versions of a program certainly implies the correctness of any specified properties of interest but what if we directly try to show validity of these properties on the transformed program?

In this thesis, we lay the foundation to study and reason about code obfuscating transformations and show how the preservation of certain behaviours may be "certified". To this end, we apply techniques of formal specification and verification, by using the Coq Proof Assistant and IMP (a simple imperative language within it), to formulate what it means for a program's semantics to be preserved by an obfuscating transformation, and give formal machine-checked proofs that these properties hold.

We describe our work on opaque predicates, a simple control flow obfuscation, and elements of control flow flattening transformation, a more complex control flow obfuscation. Along the way, we employ Hoare logic as our foundational specification language, as well as augment the IMP language with Switch statements. We also define a lower-level flowchart language to wrap around IMP for modelling certain flattening transformations, treating blocks of codes as objects in their own right.

***Index Terms*—obfuscation, verification, security, correctness, Coq, proof**

1. Introduction

1.1. Background and Motivation

We expect our systems including software systems to function "correctly". By "correctly", we mean that a system will behave according to explicit and/or implicit expectations or said another way to its written and/or unwritten specifications. Typically, extensive testing is done to increase the confidence in correct functionality of a piece of software but alas testing is known to be based on inductive reasoning where more tests passing can only increase the likelihood of correctness, so positive testing results are not a proof of correctness. In systems where more assurance of correctness is required various types of deductive reasoning is used. These are formal verification methods based on theoretical foundations rooted in logic. It is important to note that, formal verification transfers the problem of confidence in program correctness to the problem of confidence in specification correctness, so it is not a silver bullet however since specifications are often smaller and less complex to express, we have successfully reduced the trusted computing base (TCB) and increased our chances of achieving correctness.

Formal verification based methods, used to show a (software) system behaves as its specification says, typically employ a specification language based on the familiar "assertions". A specification is typically expressed in some variation of first order logic and the verification system will deductively try to prove the assertions correct or signal that they don't hold. This is a rather elaborate process where assertions (general propositional statements about program fragments that are expected to hold) are used to generate verification conditions (VC), logic formulas, that are then fed into a satisfiability modulo theories (SMT) solver, either behind the scenes in a verification backend or in more visible to the verification expert. VC generation for program verification goes back to at least Hoare's triples, Eiffel style contracts and proof-carrying-code (PCC) of Necula [9].

How can one perform code transformations such as obfuscating transformations or optimizing transformations on code that is assumed to be correct with respect to certain specified behaviour (expressed in some assertion language) while preserving the correctness of the specified behaviour?

To achieve the highest levels of assurance that the transformations have maintained correctness of the code,

is to prove the two versions of the program (before and after the transformation) is equivalent. Proving equivalency is doable in certain cases but in general is still extremely hard to do for general programs. Despite the difficulty, there are now formally verified compilers such as CompCert. However, the problem with verifying realistic systems such as a compiler is scale. CompCert verification of semantic equivalence between C and generated assembly took several man years to complete. The cost of using formal verification for mere mortals (on realistic systems) is still high.

Total equivalency between the two versions of a program certainly implies the correctness of any program properties of interest but what if we directly try to show validity of these properties? What if we limit ourselves to only proving properties of interest in the "before" version of a program are maintained in the "after" version of the program (after a transformation is applied)?

Certain simple transformations simply don't invalidate expressed properties about the "before" version versus the "after" version. Below the program snippet in listing [1] asserts that $y > 2$ which we can verify visually to be true. In the snippet in listing [2] we use a simple obfuscating transformation called variable splitting where we have split the variable x into two other variables $x1$ and $x2$ and we see that (visually) the assertion $y > 2$ still holds.

```
x = 2; y = 5;
y = x + y;
assert(y > 2);
```

Listing 1: Original Code

```
x1 = 1; x2 = 1; y = 5;
y = x1 + y; y = x2 + y;
assert(y > 2);
```

Listing 2: Obfuscated Code

In general, though, most transformations, whether optimizations or obfuscations but specially obfuscations, invalidate assertions that hold true about the "before" version. Obfuscation is especially troublesome because the goal of obfuscation is to hide the functionality of the code from prying eyes while maintaining the functionality of the "before" program. "Prying eyes" could as easily be the same as some kind of static analysis tool where an attacker is trying to determine certain facts about the code and obfuscation is trying to make this difficult. The program in listing [3] is correct with respect to the assertion that is expressed (e.g. $z == 30$) as is evident by simple inspection of the code. The program snippet in listing [4] is the "after" program where a non-linear opaque predicate transformation has been applied to hide the fact that at program's end, value of z is in fact 30. We can see that the transformation makes it a bit harder to see that the assertion still holds but knowing the fact that $\forall x \in \mathbb{Z}, ((x^2 + x) \bmod 2) == 0$, we can deduce that the assertion does hold and the value of z is in fact still 30.

This paper describes steps towards implementing a framework in the Coq Proof Assistant and based on IMP [12], a simple imperative language. to study obfuscating transformations, their impact on programs and how specified behaviour may be preserved beyond the transformations. A of number of initial goals and principles drove the direction of this research: 1) Not reinventing the wheel: start out with IMP a familiar small imperative language implemented in Coq and use its accompanying formalized semantics in [12]. 2) Accessibility to as wide an audience as possible: an obvious option was to use CompCert and Clight as [2] have done. We would have started with lots of proofs and formalisms for free (already done by the CompCert team) however the significant learning curve associated with learning CompCert infrastructure seemed prohibitive. We deemed IMP and Coq much more accessible. 3) Extendibility of the framework: Following the lead of [12] where a number of extensions to IMP are easily added and studied, we wanted the ability to build our obfuscation infrastructure incrementally on top of IMP.

Keeping these research goals in mind the contributions of this paper are the following:

- We consider different formulations of what it means for a transformation to be semantics-preserving, including complete state equivalence as well as Hoare logic equivalence. In this particular setting, the latter is a novel approach, and we give examples of its use with opaque predicate transformations. In addition, use of Hoare logic in this context leads to establishing our main approach to "certifying obfuscating transformations": our obfuscated programs will be "decorated" à la Pierce's [12] with additional assertions whose proofs will also be provided.
- We give clear and detailed explanations of the proofs and tactics in Coq, which, to the best of our knowledge, the existing literature does not, thus providing an accessible explanation of not just obfuscation techniques, but also in tandem with its formalization and verification inside Coq. This follows from research goal 2.
- We begin with a minimal imperative programming language inside Coq for reasoning about programs and their transformations, and then augment it as needed for control flow flattening algorithms, first by augmenting its syntax and semantics with switch statements, and then by defining a lower-level flowchart language that wraps around blocks of code in order to model real-world intermediate languages used in obfuscation tools. This follows our research goals 2 and 3.

```
int main (int argc, char *argv[])
{
  unsigned int x = 10;
  unsigned int y = 20;
  unsigned int z = 0;

  z = x + y;
  assert(z == 30);
  return 0;
}
```

Listing 3: Original Code

```c
int main (int argc, char *argv[])
{
  unsigned int x = 10;
  unsigned int y = 20;
  unsigned int z = 0;

  unsigned int a = ((unsigned int)argc);
  unsigned int w = a * a;

  w = a + w;
  w = w % 2;
  if (w == 0)
  {
    z = x + y;
  }
  else
  {
    z = y - x;
  }
  assert(z == 30);
  return 0;
}
```

Listing 4: Obfuscated Code

2. Background — formal verification

In this chapter we provide necessary background information used for formal verification — namely, the Coq proof assistant, the simple imperative language IMP defined inside Coq, and Hoare logic for reasoning about pre- and post-conditions of programs.

2.1. The Coq proof assistant

Coq [15] is a formal proof management system, an implementation of the *Calculus of (co)inductive constructions*, which provides a formal language in which one can write mathematical definitions, algorithms and theorems, and an environment for the development of machine-checked proofs. It is implemented (mostly) in OCaml[1] and (a little bit of) C.

2.2. CompCert certified C compiler

Something formally defined and proven in Coq leads to a high assurance of correctness — one example of this is *CompCert* [4] by Xavier Leroy's team, a formally verified compiler written in Coq for (a large subset) of C. The upshot of CompCert being formally verified is that it will not cause *miscompilation errors* — that is, the executable code produced is proven to behave exactly as the semantics specified by the source program.

3. Software Foundations — the IMP language

We now give the necessary definitions and theorems from Software Foundations [12], an interactive textbook on the mathematical foundations of reliable software, which is actually entirely a Coq script.

We use the *IMP* language defined within the Software Foundations Coq files for our code obfuscation formalisms. IMP, which simply stands for imperative, is a bare-bones simple imperative language, like C stripped of all nonessential features. This simplicity allows us to focus on the nuts and bolts of formally specifying and proving correct individual obfuscating transformations, emphasizing modularity.

Since IMP is written inside Coq, we can formally reason about not just individual programs, but entire classes of programs, and even the language itself. We give the definitions, lemmas, and theorems necessary for our work, but will omit many details and proofs.

IMP is built up piece by piece in [12] with multiple iterations (some failed, some tangential) for pedagogical purposes, but we will only present the final form that we end up using. IMP has the basics of natural number arithmetic, booleans, and commands consisting of assignment, skip, if-then-else, and while-do-end.

3.1. Command equivalence

For two commands (IMP programs) c_1 and c_2 to be equivalent means that for any pair of states st and st', c_1 takes st to st' if and only if c_2 takes st to st'. In Coq,

```
Definition cequiv (c1 c2 : com) : Prop
  := forall (st st' : state),
(c1 / st \\ st') <-> (c2 / st \\ st').
```

3.2. Hoare logic

Hoare logic is a way for us to prove that executing a program will result in satisfying certain post-conditions, (possibly) conditional on certain pre-conditions being met. This involves defining a natural way of writing program specifications, along with a compositional proof technique to prove correctness with respect to them.

Definition 3.1 (Hoare triple). A *Hoare triple*, which we sometimes refer to simply as a triple, consists of a pre-condition P, a program c, and a post-condition Q, written

$$(|P|)\ c\ (|Q|),$$

which specifies that whenever P is true before execution, running the program c is guaranteed to make Q true after execution. This informal definition leaves states implicit, but for the formulation in Coq we will need to take states into account.

Definition 3.2 (Assertion). An *assertion* about a program's state, formally, is a function from states to propositions.

```
Definition Assertion := state -> Prop.
```

Informally, for some assertion P and some state st, the proposition $P(st)$ represents the statement that P holds in state st. As an example, let st be the state where the value of every variable is 0. Let P be the assertion that $x = 0$. Then $P(st)$ is the proposition "$x = 0$ in the state st".

1. See https://www.ocaml.org.

4. Opaque predicates in IMP/Coq

We now enter the main topic of the thesis proper, formalizing and certifying the opaque predicate transformation mentioned earlier.

4.1. Opaque predicate obfuscation

An *opaque predicate* [13] is a predicate[2] that always evaluates to either *true* or *false* and the truth-value of which is known to the transformation but hard to deduce by an attacker [14]. The code under the *false* branch is never evaluated at runtime so *opaque predicates* incur no runtime performance.

Of course, the absolutely most basic opaque predicates are just the boolean constants *true* and *false* themselves, but these are not very useful in practice because it is immediately obvious what is happening in the program, and neither the simplest of humans nor tools will be fooled. For a more advanced treatment of opaque predicates and how they may be broken see [14].

An *opaque predicate* transformation takes as inputs a program to be obfuscated, c_1, an opaque predicate P, and a dummy program[3] c_2, and returns the program

```
IFB (P x) THEN c1 ELSE c2 FI.
```

In the Section 5, we describe our initial (straightforward, naive) attempt, explicitly defining the transformation to introduce the lines of code that assign variables associated with the opaque predicate (as one may naturally expect to write code in a typical imperative language), and see that trying to state a general theorem about command equivalence ends up being problematic.

However, we then discuss how this spawned two ideas in different directions that rectify the issue. On the one hand, we use Hoare logic with this first formulation, in Section 5.2, to prove weaker conditions of a transformation than total command equivalence. On the other hand, in Section 5.3 we reformulate the transformation to rely on values already existing in the state of the program, with the view that one may be applying an opaque predicate transformation to a small piece of code somewhere within a much larger program that would have such values floating around in the state already.

Finally in Section 5.4, we again employ Hoare logic to give a formal example of how an attacker who does not know about the opaque predicate's constant truth valuation, but otherwise can analyze (using static analysis) the program, ends up gaining weaker knowledge because of it.

All code for this chapter is in the file $OBFS_opaque_predicate.v$ [**?**].

2. This could be any statement in a program that could evaluate to true or false, but we will only be concerned with arithmetic formulas in this thesis.

3. It's not known to an attacker, a priori, that it's a dummy program. In practice, c_2 should be constructed so that it is not obvious; e.g. c_2 should not be simply an empty program, but should be complicated enough that it looks like it could feasibly be intended to be executed.

5. Command equivalence

5.1. Factorial program (countdown nonzero formulation)

The following IMP program computes the factorial of a nonzero natural number. The input is read from X, temporary values are stored as Z, and the factorial of the input is stored in Y as the output.

```
Definition fact_nonzero : com :=
  Z ::= X;;
  Y ::= 1;;
  WHILE ! (Z <= 1) DO
    Y ::= Y * Z;;
    Z ::= Z - 1
  END.
```

The choice of factorial program as a candidate for examples of obfuscation is somewhat arbitrary. It works well for illustrative purposes, however, as it is neither too complex nor completely trivial.

Example 5.1. The $fact\_nonzero$ program with input $X = 3$ yields output $Y = 6$. However, the story is not quite so simple (it is true that input $X = 3$ yields $Y = 6$, but as one can see in the Coq example, the state keeps track of the value of every variable involved in the program.). The specification of this statement in Coq is

```
Example factorial_3:
fact_nonzero / { X --> 3 }
  { X --> 3; Z --> 3; Y --> 1; Y --> 3;
  Z --> 2; Y --> 6; Z --> 1 }.
```

Note that formally, the final state holds the information of every intermediate assignment made by the program. We can discern the output $Y = 6$ by the fact that this is the rightmost case of a value being assigned to Y. But wait, there's more! We said earlier that in Coq, an example is no different from a proposition or a theorem in anything but name, so we must actually give a proof[4]. Moreover, since command evaluation is relational and not functional (recall the reason for this is the possibility of non-terminating While loops), we must build the proof out step by step (see [10] for proofs).

For this section, we'll use as a simple opaque predicate namely,

$$\forall x.\ (x * x + x + x + 1) = (x + 1) * (x + 1).$$

We now define an opaque predicate transformation with our running example. For the purposes of making the proofs easier to work with, and also to add a slight additional touch of obfuscation, we split up these assignments over multiple lines, as follows.

```
Definition opaque_trans x c1 c2 :=
  X' ::= (ANum x) ;;
```

4. This really is an example, to us. But just because one declares "here is an example of X" does not mean that X is necessarily true. In Coq, a proof must still be constructed.

For example, in natural language, one can say "An example of a prime number is 20051". But this isn't immediately obvious, and one still needs to prove that example, for instance, by writing a program that tries to divide it by every number up to its square root.

```
  Z' ::= X' * X' ;;
  Z' ::= Z' + X' ;;
  Z' ::= Z' + X' ;;
  Z' ::= Z' + 1 ;;
  Z'' ::= X' + 1 ;;
  Z'' ::= Z'' * Z'' ;;
  IFB (BEq Z' Z'') THEN c1 ELSE c2 FI.
```

holds and executes c_2 otherwise. Of course, the above is true for all x, so the resulting program should be the same as c_1. We'd like to claim that a program transformed by $opaque_trans$ is equivalent to the original.

The observant logically inclined reader should, at this point, now be suspicious about taking this claim at face value. What do we mean when we say the transformed program should be "the same"? The next example, which shows what happens when $opaque\_trans$ is applied to the $factorial\_3$ example, elucidates the necessity to be precise. First, however, we will need a few lemmas that show our opaque predicate is indeed such, in various incarnations to be used in proofs.

Lemma 5.2. It is indeed the case that

$$\forall x \in \mathbb{N}, (x * x + x + x + 1) = (x + 1) * (x + 1).$$

Example 5.3. For any $x \in \mathbb{N}$ and any program c_2, $opaque\_trans$ x $fact\_nonzero$ $c2$ with input $X = 3$ yields output $Y = 6$. In Coq, however, it looks as follows.

```
Example factorial\_3\_opaque\_trans:
  forall x c2,
  opaque_trans x fact_nonzero
  c2 / { X --> 3 }
    { X --> 3; X' --> x; Z' --> x * x;
      Z' --> x * x + x;
      Z' --> x * x + x + x;
      Z' --> x * x + x + x + 1;
      Z'' --> x + 1;
      Z'' --> (x + 1) * (x + 1);
      Z --> 3; Y --> 1; Y --> 3;
      Z --> 2; Y --> 6; Z --> 1 }.
```

After instantiating variables and unfolding the definitions, the transformed program looks like:

```
X' ::= x;;
Z' ::= X' * X';;
Z' ::= Z' + X';;
Z' ::= Z' + X';;
Z' ::= Z' + 1;;
Z'' ::= X' + 1;;
Z'' ::= Z'' * Z'';;
IFB Z' = Z''
THEN Z ::= X;;
  Y ::= 1;;
  WHILE ! (Z <= 1) DO Y ::= Y * Z;;
      Z ::= Z - 1
  END
ELSE c2 FI
```

We cannot use $cequiv$ (3.1) — that is, we can't use it with the current formulation of the transformation) — since new variables and assignments are introduced and kept track of in the definition of the state, even if we ultimately don't care about them.

Thus we were not ultimately successful, in this initial approach, in formulating a statement with command equivalence (3.1). We'll revisit this in Section 5.3.

5.2. Hoare logic equivalence

In this section, we explore using Hoare logic to specify program conditions, and then generalize the result as much as we can. The main idea with Hoare logic is that we can be more specific about what we wish a transformation to preserve (in our case, just the value of a single variable before the program runs and the value of a single variable after the program finishes, rather than the entire state as in the previous section). First, we'll use a slightly different formulation of the factorial program.

Definition 5.4 (Factorial program (count-up formulation)). This version of the factorial program counts up from zero rather than down from X, and works for input 0 as well.

```
Definition fact_program : com :=
  Y ::= 1;;
  Z ::= 0;;
  WHILE ! (Z = X) DO
    Z ::= Z + 1;;
    Y ::= Y * Z
  END.
```

We begin by restating Example 5.1, replacing the specific values of 3 and 6 with arbitrary natural numbers, as the Hoare triple

$$(|X = x_0|)\ fact\_program\ (|Y = x_0!|).$$

We give definitions of the assertions on the values of X and Y in Coq as follows.

```
Definition as_x (x0 : nat) : Assertion
   := (fun st => st X = x0).
Definition as_y (y0 : nat) : Assertion
   := (fun st => st Y = y0).
```

Example 5.5. We are now ready to prove

$$(|X = x_0|)\ fact\_program\ (|Y = x_0!|)$$

which in Coq is:

```
Example factorial_all_hoare:
 forall xo,
   {{ as_x xo }}
      fact_program
   {{ as_y (fact xo) }}.
```

We have proven that when $X = x_0$ before the (unobfuscated) `fact_program` runs, then $Y = x_0!$ after the fact. We now turn to showing that when we obfuscate `fact_program`, it remains the case that $X = x_0$ beforehand implies $Y = x_0!$ when the program finishes.

In the following, we use a new formulation of the opaque predicate transformation, as it now makes our life easier to collapse the assignments into single lines.

```
Definition opaque_trans' x c1 c2 :=
  X' ::= (ANum x) ;;
```

```
  Z' ::= X' * X' + X' + X' + 1 ;;
  Z'' ::= (X' + 1) * (X' + 1) ;;
  IFB (BEq Z' Z'') THEN c1 ELSE c2 FI.
```

Example 5.6. We now prove the same Hoare triple holds with the obfuscated factorial program in place of the original program.

$$\forall x_0 \in \mathbb{N},\ \forall c_2 \in Com, (|X = x_0|)\ opaque\_trans'\ (X, fact\_program, c_2)\ (|Y = x_0!|)$$

which in Coq is

```
Example factorial_all_hoare_opaque:
forall x xo c2,
  {{ as_x xo }}
     (opaque_trans' x fact_program c2)
  {{ as_y (fact xo) }}.
```

We've now successfully shown that our factorial program, both with and without the opaque predicate transformation, satisfies a Hoare triple of the form

$$(|X = x_0|)\ c\ (|Y = y_0|),$$

and we would like to generalize[5]. Let's introduce a new term: *Hoare fidelity*.

Definition 5.7 (Hoare fidelity (with respect to input X and output Y)). A program c_2 preserves the Hoare fidelity of a program c_1 with respect to input X and output Y, if the validity of the Hoare triple

$$(|X = x_0|)\ c_1\ (|Y = y_0|)$$

implies the validity of the Hoare triple

$$(|X = x_0|)\ c_2\ (|Y = y_0|).$$

In Coq,

```
Definition Hoare_fidelity_xy c1 c2
 := forall xo yo,
 hoare_triple (as_x xo) c1 (as_y yo) ->
 hoare_triple (as_x xo) c2 (as_y yo).
```

Indeed, the decision to use the factorial program in the previous examples for illustrative purposes was an unnecessary detail, so we replace it with an arbitrary program.

Theorem 5.8. For all programs c_1 and c_2, and all $x \in \mathbb{N}$, the transformed program $opaque\_trans'(x, c_1, c_2)$ preserves the Hoare fidelity with respect to input X and output Y of c_1. In Coq,

```
Theorem Opaque_trans_hoare_fidelity_xy:
 forall x c1 c2,
  Hoare_fidelity_xy c1
    (opaque_trans' x c1 c2).
```

5. Our result is still rather specific; the only pre-condition we treat is that a specific variable X takes on some value, and the only post-condition we treat is that a specific variable Y takes on some value. The pre- and post- conditions in Hoare logic could be more general, such as assertions that a variable isn't equal to some value, is greater than some value, or a conjunction or disjunction of several other statements.

5.3. A formulation without assignment

In the first presentation of the opaque predicate transformation from Section 5, we used a program that allowed the user (that is, the person obfuscating the code) to specify a particular number, and then add a number of assignments before the opaque predicate check, and then ultimately noted at the end of Section 5 that command equivalence (which depends on the full state — that is, the equality of values of *all* variables) did not hold in this model due to these extra assignments and variables.

We now present an alternate formulation with no assignments, with the entire predicate built into the boolean condition of the branching statement. On the one hand, the entire equation appears on a single line instead of a number of assignments, which may make it easier to detect, but on the other hand, it can access any variable already being used (and in the case of IMP, also any variable not already being used; recall a state in IMP is a total map from strings to $\mathbb{N}$ and all variables have default value 0). In this case, state equivalence can be proven in general.

The power of proving a theorem to this level of generality is that now, the particular programs and predicate used are irrelevant and can be swapped with anything, so long as we can prove the fact that the predicate supplied is indeed an opaque predicate.

Example 5.9. We can now apply this theorem to our same running example of predicate and factorial program as before.

```
Example example_fact_opaque_pred:
 cequiv fact_nonzero
 (make_opaque_pred_IFB
   (make_opaque_pred
     ((X + 1) * (X + 1))
      (X * X + X + X + 1))
     fact_nonzero SKIP).
```

5.4. Hoare logic - weakened information simulation

We close this chapter with a series of examples that formally demonstrates the obfuscating effect of using an opaque predicate from the point of view of a simulated attacker. We use Hoare Logic with the factorial program again, with input $X = 3$, output $Y = 6$, and with the $square\_program$ as the dummy program.

Example 5.10. With the original factorial program, it is a straightforward application of the more general theorem already proven that the Hoare triple

$$(|X = 3|)\ fact\_program\ (|Y = 6|)$$

is valid.

Example 5.11. With the transformed program, the analogous Hoare triple

$$(|X = 3|)\ trans\_fact\_square\_program\ (|Y = 6|)$$

is valid.

Example 5.12. Now to simulate an attacker[6] who does not understand the opaque predicate, we show that the best information that can be gleamed is that the output is either 6 or 9; the proof must proceed through both the if-then and if-else branch, and the final post-condition weakened to the disjunction of the two possible outcomes, yielding the Hoare triple

$$(|X = 3|)\ trans\_fact\_program\ (|Y = 6 \vee Y = 9|).$$

6. Control flow flattening in IMP/Coq

Reverse engineering tools such as the one we saw in the Introduction can at a glance reveal some information about the *control flow* of the program, or the rough structure as delineated by the flow of blocks of code through If-Then-Else, While-Do-End, Switch, and Jump constructs.

The obfuscation technique to make this difficult to analyze, then, is *control flow flattening*, which aims to break apart all of these constructs that would reveal information about a program's control flow, and flatten an entire program into a single semantically equivalent switch statement inside a while loop.

For a through treatment of control flow flattening obfuscation and its effects in obstructing static analysis see [16].

6.1. Flattening an If-Then-Else construct

For the first half of this chapter, we will focus in on a single transformation that turns an If-Then-Else construct into an equivalent flattened program (adapted from [2]):

```
int i;
i = 0;
if (i < 100)
{
  i++;
}
```

Listing 5: If-Then-Else

We will, in Section 6.2, first add the syntax and semantics of Switch statements to the IMP language. Then in Section 6.3 we formalize the above transformation, define what it means for it to be correct, realize some additional conditions are required and formulate what those are, and then finally prove it so.

6.2. Augmenting IMP with Switch (IMP+Switch)

Before we can formalize control flow flattening of an If-Then-Else construct, we need to enrich IMP with the syntax and semantics of switch statements, which we'll call the *IMP+Switch* language. We'll also define a new type, $address$, which is just a wrapper for a nat and a type lc (list of commands) which is a list of possible

6. This thesis is primarily focused on correctness rather than security models. We're just assuming that we have an attacker performing static analysis on the code, and that he or she doesn't know the opaque predicate is always true or always false. Under that assumption, we show that they obtain weaker information than they otherwise would have.

```
int i;
int swVar;
swVar = 1;
while (swVar != 0) {
  switch (swVar) {
    case 1:
      i = 0;
      swVar = 2;
      break;
    case 2:
      if (i < 100) {
        swVar = 3;
      break;
      } else {
        swVar = 0;
       break;
      }
    case 3:
      i++;
      swVar = 0;
      break;
  }
}
```

Listing 6: Flattened If-Then-Else

switch branches indexed by $address$, and then redefine the type com to support switch statements.

```
Definition address := nat.
Definition lc := list (address * com).

Inductive com : Type :=
  ...
  | CSwitch :
    string ->
      list (address * com) -> com.
```

Next, we create a function to search a lc by address.

```
Fixpoint lc_lookup
  (tlc: lc) (adr: address):
     option com := ...
```

We accordingly redefine the command evaluation semantics to include switch statements.

The following theorem and its proof already exist in [12], but we must update it for our new formulation with switch statements. The proof also introduces several new tactics and features which are worth explaining (see [17]).

Theorem 6.1. Command evaluation is deterministic, in the sense that if a command evaluates a state st to a state $st1$, but also to some (a priori, possibly) other state $st2$, then it must be the case that $st1 = st2$. In Coq,

```
Theorem ceval_deterministic:
  forall c st st1 st2,
   c / st \\ st1 ->
   c / st \\ st2 ->
         st1 = st2.
```

6.3. Flattening If-Then-Else in IMP+Switch

Definition 6.2. We build out an If-Then-Else statement to be flattened is the following function in Coq. The

header and *footer* parameters are simply any IMP commands that occur before and after the If-Then-Else statement. Since, we wish to prove command equivalence between the original and transformed programs, so we note that $swVar$ is introduced with value 0 and ends with value 5 in the transformed program; hence, we'll preprocess the original program to be transformed by adding in these assignments.

```
Definition
  preprocess_program
    header cond c1 c2 footer:
      com := ...
```

Definition 6.3. Transforming a program with control flow flattening on an If-Then-Else statement takes the If-Then-Else components and builds a 'switch' wrapped in a 'while' with 'cases' appropriately handled.

```
Definition
   transform_program
     header cond c1 c2 footer:
       com := ...
```

Definition 6.4 (WorldEater program). We'll use a minimal example program for this section, which we call *WorldEater*, a program that does nothing if the variable X is zero, and assigns $X = 1$ otherwise.

```
Definition WorldEater : com :=
  IFB (X = 0) THEN
    SKIP
  ELSE
    X ::= 1
  FI.
```

Example 6.5. To preprocess $WorldEater$, we feed its components to `preprocess_program`.

```
Definition PreprocessWorldEater :=
  preprocess_program
    SKIP (X = 0) SKIP (X ::= 1) SKIP.
```

Note that since the header and footer are mandatory, we add $SKIP$s, and the $swVar$ is set to the same initial and final values so we can prove command equivalence to the transformed program.

Example 6.6. To transform $WorldEater$, we feed its components to $transform_program$.

```
Definition TransWorldEater :=
  transform_program
    SKIP (X = 0) SKIP (X ::= 1) SKIP.
```

Example 6.7. The preprocessed and transformed $WorldEater$ program are command equivalent. In Coq,

```
Example WorldEaterTransEquiv :
  cequiv
    PreprocessWorldEater
    TransWorldEater.
```

The proof (see [17] for details) follows the same structure and ideas as the more general Theorem 6.10 to come.

We now wish to generalize this example, and state a general theorem that all programs' preprocessed and transformed forms are command equivalent. However the fact that we haven't fully accounted for the newly introduced $swVar$ which controls the switch statement is problematic. If the original program already uses this variable in some way, then everything could break.

Definition 6.8 (Evaluation invariance). A program c is *evaluation invariant* with respect to a variable X if, for all states st and st' and all $n \in \mathbb{N}$, c evaluates st to st' if and only if c evaluates st updated with $(X \longrightarrow n)$ to st' updated with $(X \longrightarrow n)$.

In other words, if the only thing that changes about the start state is the value of X, there is no impact on evaluation with the sole exception of the same change to X in the end state. In Coq,

```
Definition eval_invariant c X :=
  forall n st st',
    c / st \\ st' <->
    c / st & { X --> n }
         \\ st' & { X --> n }.
```

Lemma 6.9. Evaluation invariance implies evaluation independence in the sense that, if a command c is evaluation invariant with respect to X, then if c evaluates a state st updated with $(X \longrightarrow n)$ for some $n \in \mathbb{N}$ to st', then c also evaluates st to st'. In Coq,

```
Lemma eval_inv_imp_eval_ind:
  forall c X n st st',
  eval_invariant c X ->
  c / st & { X --> n } \\ st' ->
  c / st \\ st'.
```

Theorem 6.10. Control flow flattening of If-Then-Else constructs is sound in the following sense.

Fix the variable `swVar` for the control flow flattening transformation. For any program of the form $header;;IFBcondTHENc1ELSEc2END;;footer$, we have command equivalence between the programs

```
preprocess_program ...
```

and

```
transform_program ...
```

as long as the following hold:

- The commands $footer$, $c1$, and $c2$ are evaluation invariant with respect to $swVar$.
- The boolean condition $cond$ is boolean invariant with respect to $swVar$.

6.4. Flattening a While-Do-End construct

We now switch gears and study (as well as formalize) an example of dismantling and then flattening a While-Do-End construct described in [16]

Starting with a program with a While-Do-End construct, it is *dismantled* into a number of basic blocks (sequence of non-control flow commands ending with a control flow command), essentially replacing the While-Do-End construct with conditional GoTo statements at the end of some blocks. The targets of these GoTos are determined dynamically with conditions on some variable in memory, instead of a direct (constant) address as the jump target. Following [16] we call this intermediate transformation a dismantling.

The next level of the transformation is reminiscent of the transformation studied in the first half of this chapter, wherein these GoTos are replaced by entry into a switch statement. In keeping consistent with prior terminology,

this transformation will be called flattening. We'll develop a different language in the next section, however, and model this a bit differently from the switch statements of Sections 6.2 and 6.3, as we need to consider basic blocks as first class citizens.

6.5. Wrapping IMP in a flowchart language (IMP+Flow)

In this section, we describe a new lower-level formal language which will be used to represent the example from the previous section. We'll call this language *IMP+Flow*, short for flowchart. We also define evaluation relations for basic blocks and program of basic blocks (see [17] for details).

This language is similar to intermediate languages that are transpiled to and used in the commercial obfuscation tools such as Cloakware's obfuscation engine. While very cumbersome to actually write programs in, it is well-suited to control flow flattening algorithms due to its treatment of basic blocks (of code) as first-class citizens.

Note here that the underlying program is the original IMP, and not the IMP+Switch defined in Section 6.2. We handle switch statements differently here, by defining them as a type of block.

6.6. Flattening While-Do-End in IMP+Flow

Starting with an example program in IMP proper:

Definition 6.11.

```
Definition OriginalCommand : com :=
  WHILE (A <= 2) DO
    B ::= A + B ;;
    IFB (!(B <= 4)) THEN
      B ::= B - 1
    ELSE SKIP FI ;;
    A ::= A + 1
  END ;;
  RETURN ::= A * B.
```

We transform it into the dismantled version which is basically the same program but using basic blocks and labels and jumps. We show that the 'DismantledProgram' will, like the 'OriginalProgram', evaluate a state that begins with $A = 1$ and $B = 2$ to a final state that has $RETURN = 12$. We then manually build the flattened version of 'DismantledProgram' component by component and show that the resulting 'FlattenedProgram' will, like the 'OriginalProgram' and the 'DismantledProgram' evaluate a state that begins with $A = 1$ and $B = 2$ to a final state that has $RETURN = 12$.

7. Related works

There have been three papers, in all of which Sandrine Blazy (Université de Rennes 1) appears as a coauthor, that study code obfuscation in Coq.

Towards a formally verified obfuscating compiler

Towards a formally verified obfuscating compiler [1] also uses IMP as the language for obfuscation, but studies data obfuscation techniques, as opposed to the control obfuscation techniques which opaque predicates and control flow flattening fall under [11].

The first particular transformation studied herein is obfuscating integer constants, wherein all integer values are substituted by different ones in a distorted semantics using an obfuscating function $O : \mathbb{N} \to \mathbb{N}$. The other discussed is variable encoding, which changes the names of variables. A real-life application of this could be, for instance, to change a descriptive variable name like $account\_balance$ to a string of gibberish.

This is an inherently different class of techniques from the ones studied in the present work, and one can make a simple combinatorial argument that putting them together in the same obfuscation transformation would generate a synergistic effect on making a program more difficult to analyze.

Formal verification of control-flow graph flattening

Formal verification of control-flow graph flattening [2] also studies control flow flattening, but the authors use the Clight language of CompCert (the formally verified C compiler in Coq, discussed in Chapter Clight is the first intermediate language in the CompCert compiler, and the strategy used was to prove the correctness of the obfuscation strictly there, from which CompCert's own proofs of semantic preservation give the correctness of the rest of the compilation process "for free".

On the one hand, this makes the work less elementary and less accessible, as it works with a nontrivial subset of the real C language, but on the other it is clear evidence that formal verification of obfuscation techniques need not be restricted to a small language like IMP (which would never be used in real software development), and other real-world practicalities considered in this paper include simulation techniques and analysis of running time.

This work also discusses some techniques for combining obfuscation techniques, such as splitting a switching variable into two different variables that are updated at different points of a program, as well as randomly encoding the values of the switch cases so that they are not just consecutive numbers beginning with 1. These are necessary considerations, since we need to think one level higher about our attackers, and obfuscate the fact that we are obfuscating particular parts of our code with CFG flattening in the first place!

In comparing this work to ours, the present author believes there is merit both in the IMP and the CompCert routes. In the former, the language used is of minimal complexity, which allows not only for specifications and proofs of transformations to be developed quicker without being bogged down in unnecessarily complicated features of the underlying language, but is also better suited for pedagogical purposes. IMP is also Turing complete, so from a theoretical point of view there is no loss of generality in proofs made using it — they can always be adapted to CompCert later. But on the other hand,

CompCert is, of course, closer to languages that would be of interest to real-world software development and so more practical in that sense.

The authors ran into a similar issue as in the present work of needing to separate switching variables from those in the program to be transformed, but their solution was different — they instead use a function to parse the program to be transformed and generate a fresh variable which doesn't appear there to be used for the transformation. From a practical point of view, this is perhaps more natural, and in line with how a real obfuscating tool would function — generating new variables rather than demand that a certain specifically named variable doesn't exist in the source program. Theoretically, though, these are equivalent, since any program can contain only finitely many variable names, and there are an infinite number to choose from.

Formal verification of a program obfuscation based on mixed boolean-arithmetic expressions

Formal verification of a program obfuscation based on mixed boolean-arithmetic expressions [3] mixed boolean-arithmetic continues to work in Clight, which studies obfuscations that involve mixing arithmetic operators and bitwise boolean operators. This is another data obfuscation which appears frequently in real-world binary code, but as it is based on features wildly beyond the capabilities of IMP, a detailed discussion is beyond the scope of the present work.
